Abstract

This work aims to design a system for processing blockchain data of selected cryptocurrencies for further exploring using IPFS. In this thesis, we created a proprietary decentralized and distributed database system that supports simple queries. The solution provides a well-arranged graphical user interface for data visualization as well as REST API, which makes it easy to connect to other systems. The benefit of this work is a new view of blockchain processing which opens up new possibilities in its exploring.

Abstrakt

Cieľom tejto práce je navrhnúť systém na spracovanie a preskúmavanie blockchainu vybraných kryptomien pri použití IPFS. Na riešenie tohoto problému bolo potrebné navrhnúť vlastný decentralizovaný a distribuovaný databázový systém, ktorý podporuje jednoduché dotazy. Vytvorené riešenie poskytuje prehľadné grafické užívateľské rozhranie, ktoré slúži na vizualizáciu dát a taktiež RestAPI, vďaka ktorému sa dá systém jednoducho napojiť na iné systémy. Prínosom tejto práce je nový pohľad na zpracovávanie blockchainu čo otvára nové možnosti v jeho prehľadávaní.

Keywords

IPFS, decentralization, blockchain, cryptocurrecny

Klíčové slová

IPFS, decentralizácia, blockchain, cryptocurrecny

Chapter 1

Introduction

HTTP is “good enough” for the most use cases of distributing files over the network. However, when we want to stream lots of data to multiple connected clients at once, we are starting to hit its limits. When two clients are requesting the same data, there is no mechanism in HTTP that would allow sending the data only once. Sending duplicate data has become a problem in large companies because of bandwidth capacity. Blizzard¹ started to distribute video game content via a distributed solution because it was cheaper for the company and faster for players[7]. Linux distributions use BitTorrent to transmit disk images².

The Bitcoin blockchain has now 242 gigabytes³. When blockchain is processed (all its data are parsed), the size can grow twice as much. If there are multiple blockchains, then data can have few terabytes. When we are sharing blockchains data from the server for several clients, there is a big chance that multiple clients want the same data. They may be working on the same case and investigating the same wallets. So in standard solution with relational database and some HTTP server, the server has to search in all data (that can have a size of few terabytes) and transmits selected data to the client for every request. This problem happens even if a different client asks for the same data in a few minutes ago. Behaviour mentioned above dramatically limits the scalability of the server.

Services that are using HTTP, often have client-server architecture, so there is also a problem with a single point of failure. If the server for some reason stops working, the client can not receive data. In distributed file system such as IPFS, there is no such problem as one point of failure because all data are duplicated on multiple clients.

This Semestral project is divided into six chapters. Chapter 2 describes the differences between cryptocurrencies used in this project. Chapter 3 describes IPFS and all its layers. Design of the system created in this thesis is in Chapter 4. The implementation of all applications that are provided with this project is in chapter 5. Finally, summarization of results achieved in this work is in chapter 6.

Chapter 2

Cryptocurrencies

There were hundreds of failed attempts of creating cryptographic payment systems before cryptocurrencies like Bitcoin and Ethereum came into existence. Some of these systems are listed in Figure 2.1. All of them were created before Bitcoin. Despite that, only a few of them survived to these days. Some of these attempts were only academic proposals while others were deployed and tested systems. One of the survival is PayPal. It is only because it quickly gave up its original idea of hand-held devices for cryptographic payments.[13]

So there is a question, what makes cryptocurrencies successful nowadays? It may be easy to use principle and no need for external hardware. Another critical component of cryptocurrencies discussed in this work is Blockchain. Generally, it is a ledger in which all transactions are securely stored. The idea behind blockchains is pretty old, and it was originally used for timestamping digital documents.[5]

2.1 Bitcoin

Bitcoin is probably the most famous cryptocurrency. On 3 January 2009, Satoshi Nakamoto (an alias for a person or group persons authored the bitcoin white paper) mined the genesis block of bitcoin (block with height 0). Satoshi gets the reward of 50 bitcoins (half a million US dollars in the time of writing). This text was embedded in the block (see Figure 2.2): *The Times 03/Jan/2009 Chancellor on brink of second bailout for banks.*¹[3].

Figure 2.2: Genesis bitcoin block

First documents purchase happened in 22nd May 2010, when Laszlo Hanyecz bought two pizzas for 10 000 bitcoins (\$41 then, now about \$80 000 000)². This transactions hash is a1075db55d416d3ca199f55b6084e2115b9345e16c5cf302fc80e9d5fbf5d48d and will be stored in bitcoin blockchain forever³.

2.2 DigiByte

DigiByte was developed and released in 2013. It is based on Bitcoin with some adjustment in the code to improving functionality. In late 2017 there was 200 000 pending transaction in Bitcoin. Miners preferred transaction with a bigger fee, so to confirm a transaction, user needed to pay \$50. Digibyte solved this problem by adding a new block every 15 seconds (new block in Bitcoin is mined every 10 minutes). Average transaction occupies 570 bytes of data. One block can contain approximately 3 500 transactions given the 2 MB limit. This means that in DigiByte, 230 transactions can be confirmed in one second compared

¹https://en.bitcoin.it/wiki/Genesis_block

²<https://bitcointalk.org/index.php?topic=137.0>

³Actual photos of \$80 000 000 pizza are on <http://heliacal.net/~solar/bitcoin/pizza/>

to Bitcoin 4-7 transaction per second. DigiByte also has 1000:1 DigiByte to Bitcoin ratio, so for every Bitcoin there will be 1000 DigiByte.[2]

2.3 Ethereum

While both the Bitcoin and Ethereum networks are powered by the principle of distributed ledgers and cryptography, the two differ technically in many ways. For example, transactions on the Ethereum network may contain executable code, while data affixed to Bitcoin network transactions are generally only for keeping notes. Other differences include block time (an ether transaction is confirmed in seconds compared to minutes for bitcoin) and the algorithms that they run on (Ethereum uses ethash while Bitcoin uses SHA-256).[14]

2.4 Decred

Decred is cryptocurrency build from Bitcoin. Main difference from Bitcoin is the rewarding system from mining. In Bitcoin, the miner gets full reward for a mined block. Sometimes, the Bitcoin blockchain splits when two or more miners found a block at nearly the same time. The fork is resolved when the subsequent block(s) are added, and one of the chains becomes longer than the alternative(s). In Decred the chance of blockchain forks is minimized by hybrid proof of work and proof of state system. Each time a block is created (by a miner), it is not automatically part of the blockchain. Block needs to be approved by ticket holders. Then miner receives a block reward (newly created DCR). If the block is rejected by ticket holders, the miner does not receive a reward. Tickets holders for a new block are chosen randomly. The ticket validates the previous block. A block needs at least three of the five votes chosen to approve it for it to be validated. This hybrid system has many implications, including making a 51% hashpower attack very difficult, and making a minority fork very difficult as well.[6]

2.5 Monero

Three years after Bitcoin, in 2012, the competing Bytecoin cryptocurrency entered the market. The problem with this cryptocurrency, however, was that 80% of all coins were mined in advance by its authors. The chances of mining were, therefore, not balanced. This led to the decision that this cryptocurrency would start again. New cryptocurrency starts on 18 April 2014 and was called BitMonero, a composite of the word coin in Esperanto (Monero) and Bitcoin according to Bitcoin. However, after five days, the community decided to use only Monero for short. Monero's significant advantage is the dynamic size of the mined blocks. Bitcoin has one block size limited to 1 MB, while Monero adapts the block size to the network load. If the number of transactions increases, so does the block size to accommodate all transactions. Thus, unlike Bitcoin, the more transactions users make, the lower the transaction fee. Monero's main benefit is its full anonymity and interchangeability. Monero hides recipient and sender addresses.[11]

Chapter 3

IPFS

IPFS¹ stands for InterPlanetary File System and is a peer-to-peer distributed filesystem designed to make the Web faster, safer, and more open. In contrast with a standard filesystem, objects in IPFS are content-addressed by the cryptographic hash of their contents. In the case of the standard Web, when user wants some file, he needs to know on which server is a file located and the full path to the file (see Figure 3.1). In IPFS user needs only to know the hash of the requested file. He does not care about the location of the file (see Figure 3.2). Let us take an MIT license text, and add it to IPFS. If somebody tries to add this license as a file to IPFS, it will return `QmWpvK4bYR7k9b1feM48fskt2XsZfMaPfNnFxdbhJHw7QJ` every time. That is now and will be in the future, the *content address* of that file. Later, when user try to get this file by its hash, he can get it from a random person that added it into IPFS in the past.

IPFS can easily represent a file system consisting of files and directories. A small file (less than 256 kB) is represented by an IPFS object with data being the file contents (plus a small header and footer). Note that the file name is not part of the IPFS object, so two files with different names and the same content will have the same IPFS object representation and hence the same hash. A large file (more than 256 kB) is represented by a list of links to file chunks that are less than 256 kB, and only minimal information specifying that this object represents a large file. Currently, there is no known size limitations uploaded file or directory. There are already some big datasets hosted on IPFS such as Geocities archive² (704TB) or Project Apollo Archives³ (61GB).

IPFS provides API for manipulation with objects in several levels of abstraction. Two most used APIs are Files and Graph API. The files API⁴ enables users to use the File System abstraction of IPFS. Currently it has `add`, `cat`, `get` and `ls` methods. In the future, there should be MFS (Mutable File System), that would add methods `chmod`, `cp`, `mv`, `rm`, `stat` and `touch`⁵. Graph API⁶ is used in lower level of abstraction for manipulating with any IPFS object and creating links between objects. There are `put` and `get` methods available.

Figure 3.1: Classic web addressing

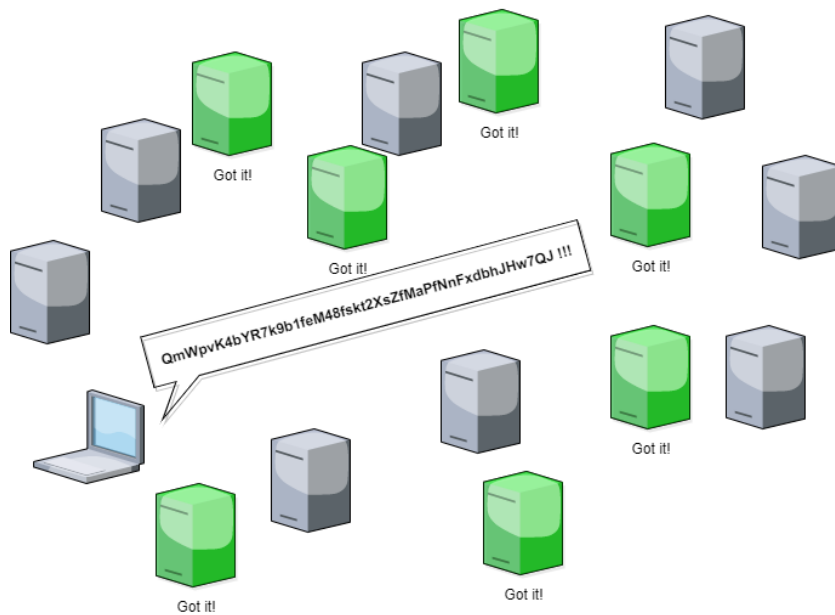

Figure 3.2: Content-based addressing

3.1 IPFS stack

We can split IPFS into layers (see Figure 3.3). *Libp2p*⁷ is at the bottom, which is a peer-to-peer networking module, that handles peer and content discovery, transport, security, identity, peer routing, and messaging. *IPLD* is the data model of the content-addressable web. It is providing linking between objects and multihash computing. On the top is *IPFS* which allows to publish and share files (or any data).[1]

3.2 libp2p

Libp2p is a modular system of protocols, specifications and libraries that enable the development of peer-to-peer network applications. It provides NAT Traversal, Peer Discov-

⁷<https://libp2p.io/>

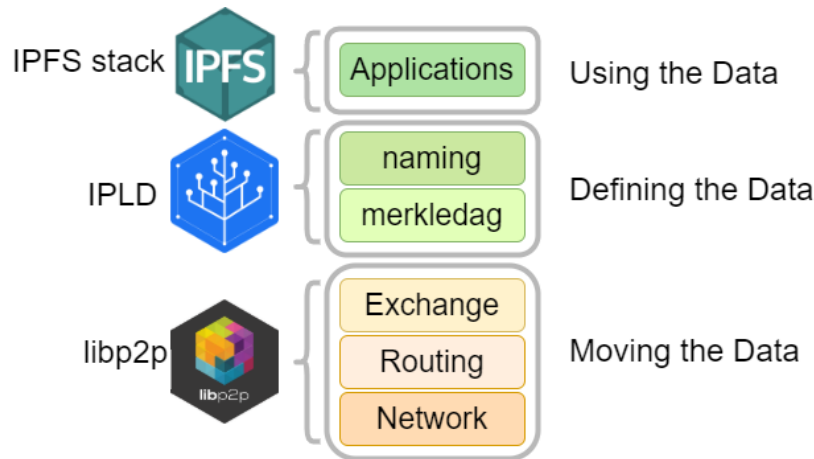

Figure 3.3: IPFS stack

ery, Routing, Stream Multiplexing, Protocol Multiplexing, Encryption, Authentication and more. It grew out of IPFS to solve networking problems in p2p networks, but now it does not require or depend on IPFS. Today many projects use libp2p as their network transporting layer, which is responsible for the actual transmission and receipt of data from one peer to another. For both content discovery and peer routing, libp2p uses Kademlia-based distributed hash table. With Kademlia, libp2p iteratively routes requests closer to the desired peer or content using Kademlia routing algorithm^[9]. In the future, Kademlia might be changed easily to some other solutions that implements a simple interface for publishing and requesting data and finding a peer.^[4]

3.3 IPLD

IPLD is providing linking and addressing objects with CID (Content ID). CID is hash-based self-describing content identifier (usually encoded to base58⁸ format) which includes codec and multihash. Multihash is then further composed of hashtype and hash value. Let us look closer on the MIT license file, that we add to IPFS at the beginning of this chapter (see Figure 3). It's CID is `QmWpvK4bYR7k9b1feM48fskt2XsZfMaPfNnFxdbhJHw7QJ`. It can be converted to human-readable format as can be seen in Figure 3.1, thanks to multicodec table⁹. We can see that this CID is encoded in base58 format and the file was stored using protobuf¹⁰ codec (this information is necessary to decode file correctly).

3.4 IPFS

IPFS is the top layer from the IPFS stack. It is used for pinning objects and files, naming system (see IPNS¹¹) and keys management. File or object is automatically pinned when a user adds it (but other IPFS commands do not include automatic pinning). Pinning a CID tells an IPFS server that the data is important and must not be thrown away. When

Table 3.1: Example of human redable version of CID

garbage collection is triggered on a node, any pinned content is automatically exempt from deletion. Non-pinned data may be deleted. The InterPlanetary Name System (IPNS) is a system for creating and updating mutable links to IPFS content. Since objects in IPFS are content addressed, an object address changes every time an object's content changes. A name in IPNS is the hash of a public key. It is associated with a record containing information about the hash it links to that is signed by the corresponding private key.

3.5 IPNS

Naming inside IPFS is governed by IPNS¹², the InterPlanetary Naming System. IPNS takes ideas from SFS¹³ to enable the creation of cryptographically signed mutable pointers, which can be used to the creation of name records inside the network.

3.6 Existing blockchain explorers in IPFS

There are already stored a few blockchains of cryptocurrencies in IPFS. For browsing them we can use dedicated applications^{14 15} or IPLD explorer¹⁶. Blockchains in IPFS are stored in raw binary format, so custom IPLD codec has to be created for every type of object. Using custom codecs for cryptocurrencies allows explorers to request blocks and transactions by its hash very fast, but there are also limitations.

- Existing IPLD codecs for cryptocurrencies are very limited. Only a few of cryptocurrency codecs are currently available in IPLD (namely Leofcoin, Ethereum, Bitcoin, Zcash, Steller, Decred and Dash)¹⁷.
- Addresses are not stored in IPFS, because they are not part of a blockchain. This means the explorer needs to go through the entire blockchain for computing address balance or to find address transactions.
- No additional information (for example transaction value in US dollars) can be stored with objects because it would change content, and therefore hash of the object.

¹²<https://docs.ipfs.io/guides/concepts/ipns/>

¹³https://en.wikipedia.org/wiki/Self-certifying_File_System

¹⁷<https://github.com/multiformats/multicodec/blob/master/table.csv>

- There is no sorting or filtering. Explorer can only show the object (block or transaction) by its hash.

Chapter 4

Design

This chapter describes the proposed design of the whole system for storing and exploring blockchains in IPFS that is to be created as a result of this thesis. All parts of the system are described in this chapter.

4.1 Overview

The system consists of one or more Feeders and Explorers. Feeders are connected to Blockbook and provide synchronization between cryptocurrency and IPFS data. Explorer can request data from the system network and display them to user.

Figure 4.1: System design

4.2 Blockbook

Blockbook¹ is a blockchain indexer for Trezor Wallet², developed by SatoshiLabs³. It currently supports more than 30 coins (and the community implemented some others). For data storage Blockbook is using RocksDB⁴ developed by Facebook, which is a NoSQL database which stores only key-value pairs. Blockbook is providing fast API for accessing blocks, addresses and transactions. Main limitations of blockbook:

- **Not distributed** (client-server architecture) - problem with scaling for more users.
- **Not a SQL database** - it does not have a relational data model, it does not support SQL queries, and it has no support for indexes.
- **Single-Process** - only a single process (possibly multi-threaded) can access a particular database at a time.

4.3 Feeder

A Feeder is a command-line service that stores data in IPFS for all cryptocurrencies specified in the config file. It uses Blockbook API for obtaining data. Feeder stores data in structure such as in Figure 4.2. Each block (except genesis and last block) has a link to the previous and next block. Also, it has links to transactions that had been processed in this block. A transaction has links to address and previous/spent transaction for every input/output. This scheme allows to store blockchain data in IPFS in small objects with size less than 256kB (a limit for storing objects directly in DHT). Also, every logical link between objects is preserved.

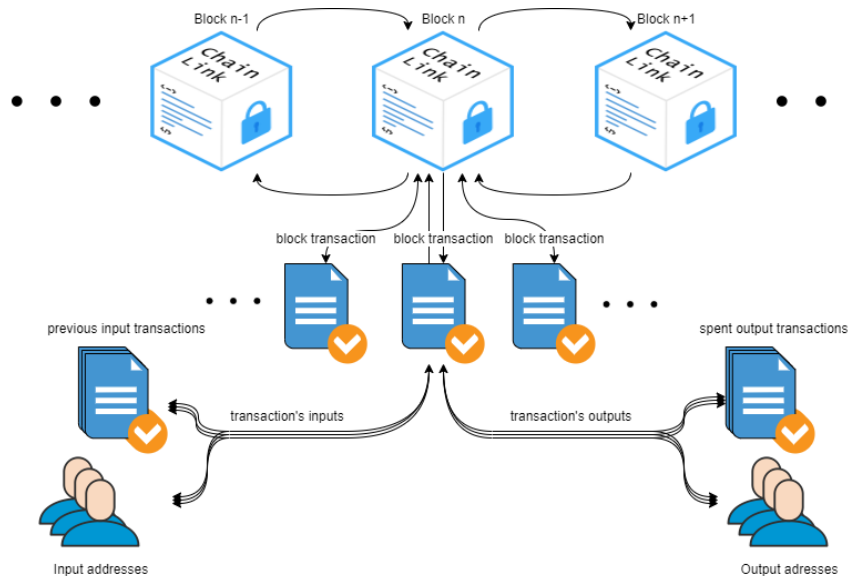

Figure 4.2: Feeder data storage structure

¹<https://github.com/trezor/blockbook>

²<https://wallet.trezor.io/>

³<https://satoshilabs.com/>

⁴<https://github.com/facebook/rocksdb/wiki>

4.4 Explorer

Explorer can perform basic queries like a search for block by its height or hash and search address and transaction by hash. Nevertheless, Explorer can also make more complex queries, for example, get 20 transaction where the sum of inputs is more than 0.5, or get transactions between some time interval. Explorer is an application that can be used in two environments. In browser with simple GUI, or in node.js⁵ as a RestAPI.

4.4.1 ExplorerGUI

ExplorerGUI is browser version of Explorer. It is implemented as a SPA⁶ to prevent restarting connection with IPFS. It has separated views for block, transaction and address details. Also paginating, filtering and sorting objects by all its properties is supported.

4.4.2 ExplorerAPI

ExplorerAPI is a node.js application provides several endpoints for obtaining the data:

- GET /tx - get collection of transaction,
- GET /tx/[:txHash] - get transaction by hash,
- GET /block - get block collection,
- GET /block/[:blockHeightOrHash] - get block by height or hash,
- GET /address - get address collection,
- GET /address/[:hash] - get address by hash.

All endpoints support more detailed path specification by providing multiple parameters at the end of the path (for example, it is possible to request only a block hash by calling /block/42/hash). Also, every endpoint supports query parameters

- **filter** where value of this parameter can be simple arithmetic expression like **height>50**,
- **limit** parameter for pagination with default value set to 20,
- **orderBy** sorts results of a sequence in ascending order.

⁵<https://nodejs.org/>

⁶https://en.wikipedia.org/wiki/Single-page_application

Chapter 5

Implementation

This chapter describes the implementation details of the system, shows the internal architecture. As mentioned in the previous chapter, the program was created in Typescript, and they are using [js-ipfs](https://github.com/ipfs/js-ipfs)¹ implementation of IPFS node. This selection of tools enables code sharing between these two separated applications.

5.1 Feeder implementation

Informations about supported cryptocurrencies and enabled indexes are stored in Feeder's configuration file. Based on these settings, Feeder will check for new cryptocurrencies blocks after the start. If Feeder finds some unstored blocks, it starts following pipeline for each missing block:

- downloads missing block from Blockbook with its transactions,
- saves block and its transactions in IPFS,
- updates indexes.

5.1.1 Indexes

Indexes are used for quick access to the data. Several different ways of indexing data are currently possible in IPFS:

- **OrbitDB**² is a serverless, distributed, peer-to-peer database build on top of IPFS, developed by HAJA networks³. OrbitDB is a good solution for small user's databases, but it is still in the alpha stage of developing, and it is not well optimized to store hundreds of gigabytes of data. The biggest problem is that OrbitDB performs all queries locally. To perform query like `db.query((tx) => tx.amount > 0.001)` OrbitDB needs to load all database locally and then cycling between them. So every client ends up with a full copy of the database. This limitation is not usable for our case when we have a database that has hundreds of gigabytes of data. [8]
- **Textile**⁴ is a set of open-source tools that provide a decentralized database, remote storage, user management, and more, over the IPFS network. Textile already created

¹<https://github.com/ipfs/js-ipfs>

²<https://orbitdb.org/>

³<https://haja.io/>

⁴<https://textile.io/>

applications for storing photos⁵, notes⁶ or anything else⁷. Textile provides a high abstraction on top of the IPFS and provides simple API to store and index files securely. It uses *Cafe* peers to provides backups and indexing. Every data store is duplicated on several *Cafe* peers. When a client is obtaining some data, it will contact one of the *Cafe* peers, and *Cafe* peer will resolve a query for the client. This is a problem for our solution because using textile require lots of harddisk memory and does not solve the problem with overloading *Cafe* peers. [12]

After some research, we concluded that currently for storing and indexing data in IPFS without large harddisk memory consumption, there is no solution. We created our own indexing system that currently supports three types of indexes.

- **Dictionary** – A simple key-value structure that can be used for translating (for example, block height to block). Search complexity is $O(1)$, which is the fastest achievable speed. Big disadvantage is that client needs to download a whole dictionary to performs search. In the time of writing this thesis, Ethereum has 9 250 000 blocks. If we want to make dictionary for translating block height to IPFS block address, the size of this dictionary would be at least $(\text{int_size} + \text{multihash_size}) * 9\,250\,000$ where minimal size for `int_size` is 4 bytes and `multihash_size` is 36 bytes when sha-256 is used (32 bytes) and multihash prefix is 4 bytes long. So this dictionary would have over 1.3 GB only for Ethereum. Another disadvantage is the impossibility to performing range search (for example get blocks between 9 249 950 and 9 250 000).

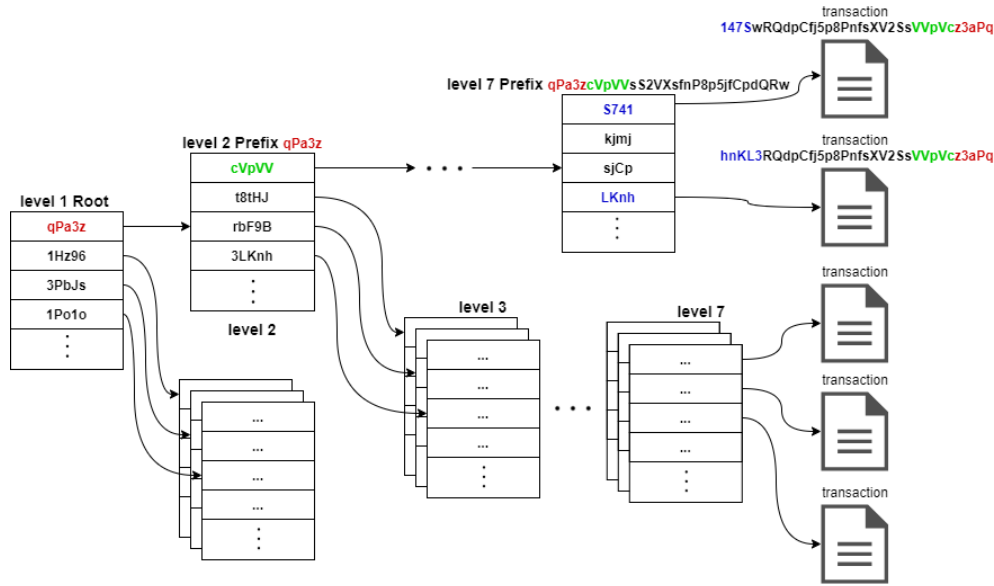

Figure 5.1: Reverse lookup by transaction hash

- **Reverse lookup** – This structure is inspired by Reverse DNS lookup⁸ and its principle can be seen in Figure 5.1. For every item that will be stored in this index, the key is reversed (for better selectivity) and split into the smaller substrings. Leading

⁷<https://anytype.io/>

⁸https://en.wikipedia.org/wiki/Reverse_DNS_lookup

substring of every key is stored in root (level 1) dictionary and is pointing to another dictionary that consists of following substrings which have the corresponding prefix in parent dictionary. Last level dictionary substrings are pointing to IPFS objects. In this index, there is a problem with performing range select operations, because items have reversed key.

- **B+ Tree** - It is perhaps the most powerful index structure. With auto balanced B+ tree, we can efficiently search objects by given key and performs range selects. Example of this structure can be seen in Figure 5.2. By default, there is the limit of 32 items in one node (but can be changed from 4 to 256).

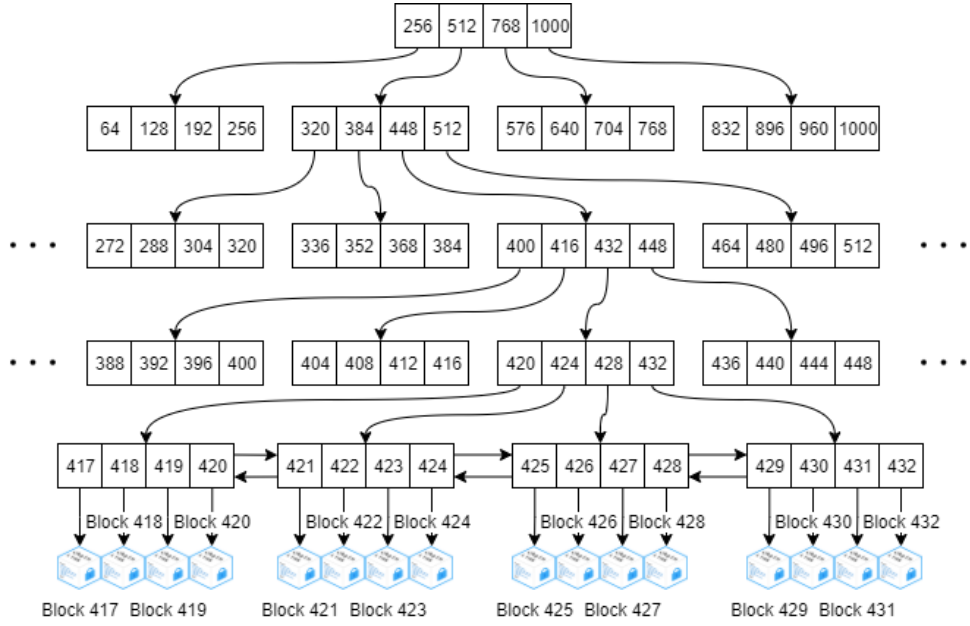

Figure 5.2: B+ tree index structure

Implementing these indexes in IPFS was surprisingly simple thanks to IPLD objects and links. When Feeder stores data into IPFS, it may also perform an index update that will change content address of the index. To prevent this, we use IPNS for creating and updating mutable links to indexes.

5.2 Explorer implementation

We can split Explorer to several modules. The central part is ExplorerCore which communicates with IPFS and provides an interface to explore blockchain and to perform queries. There can be ExplorerGUI or ExplorerAPI on the top of the ExplorerCore. These modules are providing communication with user or other systems. This architecture is shown in Figure 5.3.

5.2.1 ExplorerCore

ExplorerCore is main module of the Explorer. It is responsible for obtaining and resolving data from IPFS and performing queries. It has simple interface:

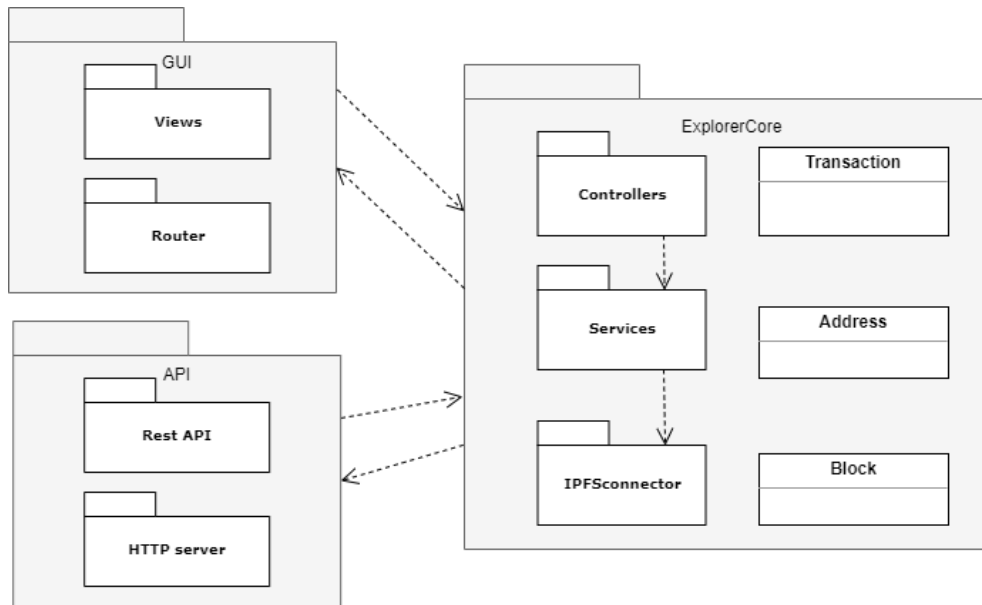

Figure 5.3: Explorer architecture

- `getObject(CID[, path])` - gets object from IPFS with optional path,
- `getTx(txHash)` - gets transaction by its hash,
- `getBlock(blockHash)` - gets block by its hash,
- `getBlock(blockHeight)` - gets block by its height,
- `getAddress(addressHash)` - gets address by its hash.

All ExplorerCore methods except `getObject` are returning `QueryObject`.

Query system

Explorer supports a simple query system. Every queriable object (address, transaction, block) has methods:

- `where(propertyName)` - create a condition on the property. There can be multiple conditions in one query. A condition has to be followed by one of the functions:
 - `gt(value)` - property is greater or equal than `value`. The query finds in an index first object that has property (set by `propertyName` in condition) equal or greater than `value`, and traverse index to the right (to bigger objects).
 - `lt(value)` - property is less or equal than `value`. Similar as in the `gt` function, the query finds the closest object that has property equal or less than `value`. Then, the query traverses index to the smaller objects with smaller index value (to the left).
 - `between(min, max)` - property is greater or equal than `min` and less or equal than `max`.
- `offset(offsetValue)` - query will skip `offsetValue` number of results,

- `limit(limitValue)` - set maximum number of results. After query has `limitValue` count of matched objects it will stop browsing the index,
- `all()` - return all objects that matched query,
- `first()` - return the first object that matched a query,
- `and(childQuery)` - logical and between two queries. Parent query resolves `childQuery` (call `all()` function) and makes a hashtable from its results. Later, when parent query being resolved, query checks if the result exists in the hashtable for every result.
- `or(childQuery)` - logical or between two queries. `childQuery` will be resolved by parent query, and its results stores in hashtable. When the parent query is resolved, its results will be added to the hashtable. This will remove duplicates in the final results.
- `[Symbol.iterator]()` - iterator that is used in cycle for (result of query).

The data obtaining will happen only when we access the data inside the Query object (for example, in for-loop) or by calling `all()` or `first()` method. Index is used only for the first condition in a query, that is on the property, that has created index. Other conditions are performed client-side.

5.2.2 ExplorerGUI

ExplorerGUI is a single page application with simple user interface that runs in browser implemented with Vue.js⁹. Browser's implementation of IndexedDB is used as a storage for IPFS as can be seen in figure 5.4. Communication with other peers is provided though WebRTC¹⁰ or WebSockets. Every tab opened in the browser is the same IPFS node. Opening a new tab in Incognito mode or different browser will spawn different IPFS node.

5.2.3 ExplorerAPI

Node.js¹¹ implementation of IPFS uses filesystem to store data (see Figure 5.5). On the top of ExplorerCore, there is a simple web framework Express¹², where are routes (endpoints) defined. Currently available routes are described in Section 4.4.2. Every route supports query parameters `filter` (used for filtering results) and `limit` (which reduces number of results). Pagination can be made by setting `filter` to be greater/smaller (depending on ordering) as key of the last displayed object and `limit` to page size. For example, if a user is looking at page of transactions ordered by time (ordered from the newest transactions to the oldest), the next page of transactions are first N transactions that happened before last displayed transaction (where N is page size).

Rest API supports optional path param `path` that is useful for traversing objects in IPFS. If we want to get fifth transaction of the block with height 1000 one of the way is request URL `/block/998/next_block/next_block/txs/5` (get block with height 998, get next block two times, get transaction, a get fifth item from array of transactions). This approach allows the user to explore IPFS storage as graph very quickly by objects links.

Chapter 6

Conclusion

The goal of this project was to create a system that uses IPFS to explore blockchain. To achieve this, we needed to create our own decentralized and distributed database system that supports queries and indexes on top of the IPFS. Feeder and ExplorerCore communicate with this database system to store (Feeder) or retrieve data (ExplorerCore). To visualize data in GUI, ExplorerGUI can be used, and for obtaining data with RestAPI there is ExplorerAPI.

The research section of this project focuses mainly on the IPFS principles (content-based addressing, nodes linking, and others). Selected cryptocurrencies for exploring are also briefly discussed. Great effort was devoted to designing the whole system and creating a functional prototype.

In the next semester, we want to highly improve database system by support more operators (`like`, `groupBy`). We want to research and compare more indexing strategies and make performance testing and profiling. Also, comparison with Blockbook in the same conditions would be interesting. There is high potential by using IPFS in this system to create new use cases that no other system for exploring cryptocurrencies blockchain supports. For example, with some heuristic, we believe, that with this system, we can follow crypto coins after exchange for another crypto coins (thanks to linking between objects in the IPLD layer).
